Neprilysin Inhibition — A Novel Therapy for Heart Failure

Mariell Jessup, M.D.

The Food and Drug Administration (FDA) last approved a new oral drug (hydralazine–isosorbide dinitrate) for patients with heart failure and a reduced ejection fraction in 2005 — and this drug was recommended only for self-identified black patients who continued to have symptoms despite evidence-based treatment.1 The aldosterone antagonist eplerenone was approved for the treatment of heart failure in 2003. (In 2012, the European Medicines Agency approved ivabradine, which has not received FDA approval.) Now, a novel drug, LCZ696, a dual inhibitor of angiotensin II receptor and neprilysin, may prove to be the first disruptive agent to the heart-failure treatment algorithm, which has remained essentially unchanged for a decade.

In PARADIGM-HF (Prospective Comparison of ARNI [Angiotensin Receptor–Neprilysin Inhibitor] with ACEI [Angiotensin-Converting–Enzyme Inhibitor] to Determine Impact on Global Mortality and Morbidity in Heart Failure Trial), McMurray et al. report that LCZ696, as compared with a target-dose enalapril-based regimen, significantly reduced the rates of death from any cause and from cardiovascular causes and the rates of hospitalizations for worsening heart failure in patients with a reduced ejection fraction. In addition, patients' quality of life, as measured on the Kansas City Cardiomyopathy Questionnaire, was significantly improved.2

Who were the patients in this remarkable trial, and how do they compare with the patients

enrolled in other noteworthy, successful trials in patients with heart failure (Table 1). The investigators included patients with New York Heart Association class II, III, or IV heart failure who had an ejection fraction of less than 40% (which was changed to 35% or less by an amendment to the protocol) and who were receiving the best available medical therapy. The patients who participated in PARADIGM-HF were similar to those in other studies involving patients with mild to moderately severe heart failure.

Why did LCZ696 succeed in improving outcomes so convincingly in this representative population of patients? Drugs that inhibit the renin–angiotensin–aldosterone system (RAAS) have been foundational to cardiovascular drug therapy for almost three decades. RAAS inhibitors moderate vasoconstriction, myocyte hypertrophy, and myocardial fibrosis, an effect that has translated into clinically meaningful improvements in functional status and survival. Natriuretic peptides, which include atrial natriuretic peptide, B-type natriuretic peptide, and urodilatin, are secreted by the heart, vasculature, kidney, and central nervous system in response to increased cardiac-wall stress and other stimuli. Natriuretic peptides have potent natriuretic and vasodilatory properties, inhibit the RAAS, reduce sympathetic drive, and have antiproliferative and antihypertrophic effects as well. Neprilysin inhibition results in an increased concentration of natriuretic peptides. Thus, the beneficial effects of RAAS inhibition are likely to be augmented by the enhancement of natriuretic peptide activity. LCZ696 is a fixed-dose combination of valsartan and AHU-377 (a neprilysin inhibitor prodrug) in a 1:1 ratio and is the first and most clinically developed agent in a new class of compounds.

Before random assignment in PARADIGM-HF, all patients had been receiving an angiotensin-converting–enzyme inhibitor or an angiotensin-receptor antagonist, in addition to their three to seven other cardiovascular drugs. The run-in phase of the trial ensured that all patients could maintain the dosing regimen, with the successive administration of enalapril (at a dose of 10 mg twice daily) and LCZ696 (at a dose of 200 mg twice daily). The authors reported that 200 mg of LCZ696 delivers the equivalent of 160 mg of valsartan. Predictably, 12% of patients withdrew during the run-in phase because of an adverse event; withdrawal was more likely when patients were receiving enalapril than when they were receiving LCZ696. Although heart-failure guidelines suggest a target twice-daily administration of either 10 mg of enalapril or 160 mg of valsartan, numerous registries acknowledge that lower doses are commonly used in clinical practice. After randomization, fewer patients in the LCZ696 group than in the enalapril group stopped their study medication because of any adverse event (10.7% vs. 12.3%, P=0.03). Thus, LCZ696 was at least as well tolerated as target doses of enalapril in PARADIGM-HF.

The investigators report that as compared with baseline values, the mean systolic blood pressure at 8 months was 3.2±0.4 mm Hg lower in the LCZ696 group than in the enalapril group. They propose that this difference in blood pressure was not a determinant of the salutary benefits of LCZ696. Interestingly, neprilysin inhibition alone does not cause clinically important reductions in blood pressure, possibly because of neprilysin-dependent breakdown of polypeptide vasoconstrictors, such as angiotensin II.
A Call to Action for Acute Lymphoblastic Leukemia

Timothy A. Graubert, M.D.

The cure rates for precursor B-cell acute lymphoblastic leukemia (ALL) among children have improved, but the prognosis for older patients and children with relapsed disease remains poor. Risk stratification based on clinical features and disease characteristics can improve outcomes by enabling physicians to reduce the toxicity of therapy for patients with lower-risk disease and intensify therapy for patients with higher-risk disease. The negative prognosis associated with the t(9;22) translocation, which results in expression of the BCR–ABL1 activated kinase fusion protein, is attenuated by treatment that includes tyrosine kinase inhibitors, providing a paradigm for molecularly guided therapy in patients with precursor B-cell ALL. Several years ago, a subtype of precursor B-cell ALL was identified that shares a gene-expression profile with Ph-positive ALL (the term commonly used to describe ALL associated with the Philadelphia chromosome, which results from the t[9;22] translocation).1,2 The pattern of gene expression in patients with Ph-like ALL prompted the hypothesis that other oncogenic drivers could substitute for BCR–ABL1, triggering a similar signaling cascade. Indeed, previous studies have identified rearrangements and mutations that activate cytokine receptor signaling in some cases of Ph-like ALL.3,4

In this issue of the Journal, Roberts et al.5 define the frequency and genomic landscape of Ph-like ALL in a cohort of 1725 children and young adults with precursor B-cell ALL. They observed a marked rise in the proportion of Ph-like cases with age, from 12% among children to 27% among young adults (Fig. 1A). Nearly half (49.4%) of the young adults had either Ph-positive or Ph-like disease. The Ph-like cases were frequently found to be associated with IKZF1 alterations (in 68% of patients with Ph-like ALL) and high CRLF2 expression (in 47%), with the latter caused by genomic rearrangement in all
